Abstract

This is the abstract.

It consists of two paragraphs.

Keywords: keyword1, keyword2

1. Introduction

In *Quantifying spatial gaps in public transport supply based on social needs* Currie (2010) introduced transit Supply Index (SI) and demonstrated how it could be used to assess gaps where between public transport supply and social need. The SI provides a score based on the number of transit arrivals at stops within an area of interest, adjusted to account the walking distance catchment of each stop. Combining the SI scores with census data, Currie (2010) mapped areas of Greater Melbourne in Victoria, Australia, where in 2006 there was a very high social need for transit but very low or zero supply.

Unfortunately, this approach does not appear to have been widely used, perhaps in part because at the time it was first published calculating the transit Supply Index (SI) was not an easy task. Timetable data was not typically available in a standardized and machine-readable format, and the Currie (2010) analysis was based on combining multiple operator databases and service frequency data manually extracted from agency websites. While extending the analysis to other cities might have allowed the needs-gap analysis for Melbourne to have been compared to other cases, clearly this would have been a large task due to the need to obtain and process data for other places.

Nowadays, the development of the General Transit Feed Specification (GTFS) means that timetable data is widely published in a standardized format, with more than 10,000 agencies providing feeds (MobilityData, undated). Historical timetable data is now also available (see [<https://transitfeeds.com/>]), meaning that longitudinal comparisons are more readily feasible. Many visualization, processing and analysis tools that accept GTFS data are now available. A gap, however, is that there is not yet a tool to calculate SI scores directly from GTFS datasets. It is also unclear whether the gaps between social needs and transit supply identified in Currie (2010) in Greater Melbourne have gotten better in the almost two decades since the original analysis, or whether the spatial patterns in Melbourne are representative of other cities.

This provides the motivation for the research reported in this paper, in which a new R package (`gtfssupplyindex`) specifically developed to calculate SI scores is presented. The paper also reports results for Greater

³Professor

Melbourne in 2016 and 2021, matching the most recent censuses and allowing comparison to the 2006 result reported in Currie (2010). Comparisons are also made to other parts of Australia, so as to explore whether findings about Greater Melbourne can be confidently generalized to other places.

The remainder of this paper is structured as follows: the next section outlines the background to this research, including the original formulation of the Transit Supply Index, and an explanation of the GTFS. Section 3 then describes the study methodology, followed by presentation of results in Section 4. Section 5 discusses the results, outlines directions for future research and provides a brief conclusion.

2. Background

2.1. Transit metrics

Even a brief search reveals many metrics available for benchmarking transit services. Examples include: (1) those in the Transit Cooperative Research Program (TCRP) Report 88, which is an extensive guidebook on developing a performance-measurement system (Ryus et al., 2003); (2) online databases provided by the Florida Transit Information System (FTIS) (Florida Transit Information System, 2018) and International Association of Public Transport (UITP) (2015); (3) those used in the extensive annual benchmarking program undertaken yearly by the Transport Strategy Centre in the United Kingdom, including over 100 transit providers around the world (Imperial College London, undated); and (4) a recently developed methodology to calculate ‘blank spots’, beyond typical walking access distances to/from transit stops (Alamri et al., 2023).

The Fielding Triangle (Fielding, 1987) provides a framework for combining indicators of service inputs, outputs and consumption to describe cost efficiency, cost effectiveness and service effectiveness. More broadly:

- Litman (2003) and Litman (2016) discuss some of the traffic, mobility, accessibility, social equity, strategic planning and other rational decision-making-based perspectives underling transport indicators;
- Reynolds et al. (2017) extends these into models of how institutionalism, incrementalism and other public policy analysis concepts might apply to decision-making processes relating to transit prioritization;
- Guzman et al. (2017), developed a measure of accessibility in the context of policy development and social equity for Latin American Bus Rapid Transit (BRT) networks; and
- Creutzig et al. (2020) introduced street space allocation metrics based around 10 ethical principles

However, many of these metrics appear difficult to calculate, complex to explain or understand, and likely not well suited to communication with those who are not planners or engineers, or other technical specialists. Where pre-calculated metrics are immediately available it may not be possible for practitioners, researchers or advocates to independently generate metrics for proposed system changes. Sometimes it is not even possible to know precisely how scores for the existing services levels are calculated. For example, Transit Scores for locations with a published GTFS feed are readily available on the Walk Score (2023) website, eliminating the need for any calculations. The meaning of these Transit Scores appears easy to explain, as the highest possible score of 100 represents what might be experienced in the centre of New York. However, the Transit Score algorithm is patented and effectively a black box. Transit Scores cannot be calculated independently or generated for proposed changes to networks.

2.2. GTFS

The General Transit Feed Specification (GTFS) is an open, text-based format developed originally to allow transit to be included in the Google Maps navigation platform (MobilityData, undated). Figure @ref(fig:GTFS_ERD) shows an Entity Relationship Diagram (ERD) of the GTFS data structure. This indicates how GTFS data is stored as a series of tables (agency, routes, trips etc.) with primary and foreign keys (agency_id, route_id, trip_id etc.) providing links.

GTFS allows individual transit systems to be included in many online products and analysis, including the Transit Score metric itself. Wong (2013) provides another example of what can be done with GTFS data, having developed code to calculate of some of the TCQSM metrics and compared these across 50 transit operators.

2.3. The Transit Supply Index

A generalized form of the Transit Supply Index (SI) , adapted from Currie (2010) is:

$$SI_{area,time} = \sum \frac{Area_{Bn}}{Area_{area}} * SL_{n,time}$$

where: (1) $SI_{area,time}$ is the Supply Index for the area of interest and a given period of time; (2) $Area_{Bn}$ is the buffer area for each stop (n) within the area of interest. In Currie (2010) this was based on a radius of 400 metres for bus and tram stops, and 800 metres for railway stations; (3) $Area_{area}$ is the area of the area of interest; and (4) $SL_{n,time}$ is the number of transit arrivals for each stop for a given time period.

The SI score does not incorporate service span, speed or other elements of a transit service. While these can be important to passenger experience, they might add complexity. Simplicity is also helped by the way that the SI is additive, in that $SI_{area,time}$ scores can be aggregated to calculate an overall score across multiple time periods or for a region encompassing multiple areas of interest.

Currie (2010) presented

3. Methodology

This study developed a package with tools for calculating the SI from GTFS data. The R programming language (R Core Team, 2023) was adopted for code development. Package development setup and workflow as described by Wickham and Bryan (2023) was adopted. Various existing packages were relied upon including: the sf package (Pebesma, 2023) for geospatial analysis; the tidyverse (Wickham et al., 2019); gtfstools (Herszenhut et al., 2022); and tidytransit (Poletti et al., 2023). Some code was adapted from examples, vignettes and other documentation in the tidytransit, gtfstools and other packages.

Two cases were used during the code development and testing, such that results might be generated for real GTFS data: the Mornington Peninsula Tourist Railway GTFS feed and the Public Transport Victoria (PTV) GTFS feed, both in Victoria, Australia. Both were selected primarily for convenience, given that the authors are familiar with the typical service patterns and geography. The Mornington Peninsula Tourist Railway network, consisting of only three stations, also facilitated hand calculation of the SI as a cross-check of the results produced by the developed package.

Figure @ref(Melbourne_map)) shows the areas of interest relevant to the code development and testing, and selected railway stations. Statistical Area (SA) zones from the Australian Bureau of Statistics (Australian Bureau of Statistics, undated) Areas of interest included Greater Melbourne (main) and SA1 zones within 800 metres of the Mornington Penninsula railway (right). SA1 zones are the smallest geographical areas for which results are reported in the Australian census, while the main image of Figure @ref(Melbourne_map)) shows the boundary of the Greater Melbourne Greater Capital City (GCC) zone and SA3 zone boundaries, which are generally similar to Local Government Area (LGA) boundaries (albeit with some LGAs split into two zones).

3.1. Mornington Penninsula Tourist Railway

The Morning Peninsula Tourist Railway is in the outer south-east of Melbourne, running on Sundays and Wednesdays between Mornington and Moorooduc, with an intermediate stop at Tanti Park (see <https://transitfeeds.com/p/mornington-railway/806/latest/stops>). A GTFS feed from 2018 was selected for the purposes of tests and demonstrating the code and output. Australian Bureau of Statistics (ABS) data was also used, sources via the strayr and absmappedata packages (Mackey et al., 2023). The Mornington Peninsular Statistical Area 3 (SA3) zone and the Statistical Area 1 (SA1) zones contained within it were adopted as the areas of interest.

3.2. Public Transport Victoria (PTV)

The Victorian GTFS feed, published by Public Transport Victoria (PTV) and with historical feeds sourced via Transit Mobility Data, (2023), was used for analysis of Victoria. SI scores were obtained for the weeks starting on the day of the census in 2016 and 2021, which were on Tuesday 9th and 10th of August respectively.

4. Results

4.1. Code structure and functionality

Developed code is available and documented on github (Reynolds, 2024). The structure of the package, functions developed, and data tables are shown in Figure @ref(fig:SI_ERD). This shows how the package takes input from three files: a gtfs feed (gtfs.zip); a sf object describing the geometry of the areas for which the SI is to be calculated; and a csv file (included in the package) defining the buffer zone distances for each route type. The ultimate output is a `si_by_area_and_hour` table (bottom-right), which reports the SI score for each hour of the day across dates specified by the user.

Various functions and their output are explained in the following, using the Mornington Peninsula GTFS for December 30th, 2018, and SA1 zone boundaries as a worked example. Individual steps are:

- (1) loading the gtfs.zip file: the `gtfs_by_route_type` function loads the gtfs data and splits it into a list (by `route_type`) of tidygtfs objects, using the `filter_by_route_type` function from the `gtfstools` package (Herszenhut et al., undated).
- (2) loading geometry information about the areas of interest: geographical data about the areas of interest are loaded by the `load_areas_of_interest.R` function into an sf object, using the `sf` package (Pebesma, 2023). The resultant `areas_of_interest` table contains each `area_id` and its associated geometry. Data about buffer zones, specifically the walking distance threshold assigned to each `route_type` (mode) is then loaded, again through a function (`load_buffer_zone.R`).
- (3) calculating which stops are within the catchment walking distance of which areas: using the `stops_in_walk_dist` function. Figure @ref(fig:calculate_stop_in_or_near_areas_verbose)) shows how this function identified SA1 areas within the 800 metre catchment of the three Mornington stations.
- (4) Calculating SI scores for a given time period: The `si_calc.R` function calculates the number of arrivals in a given time period, using code adapted from an article included in the `tidytransit` package (Poletti, undated), and combines this with the calculated area components. The `si_total.R` and `hourly.R` functions provided aggregation, giving the results mapped in Figure @ref(fig:SI_mornington_20181230_output).
